Health Disparities in the Medi-Cal Population

Acknowledgments

AUTHORS
The Department of Health Care Services (DHCS) would like to acknowledge the authors of Health Disparities in the Medi-Cal Population for their excellent work in developing these fact sheets and their dedication to improving the health of Californians.

Desiree Backman, DrPH, MS, RD

Health Disparities in the Medi-Cal Population

**Infant Mortality**

The Centers for Disease Control and Prevention define infant mortality as the death of a baby before his or her first birthday. About 25,000 infants die each year in the United States, and there are significant differences by age, race, and ethnicity. African American infants have twice the infant mortality rate as White infants.¹

Of the 6 babies that die for every 1,000 births, most die as a result of serious birth defects, being born too small or early, Sudden Infant Death Syndrome, maternal complications, or are victims of injuries.¹

In 2010, the infant mortality rate for the state of California was 4.7 per 1,000 births.² The infant mortality rate for Medi-Cal members in 2010 was slightly higher at 5.5 per 1,000.³ Infant mortality rates varied by race/ethnicity with African Americans and people classified as “Other” or “Unknown” having substantially higher rates as compared to Whites, Latinos, and Asians/Pacific Islanders. For all of the racial/ethnic groups, infant mortality rates were higher among Medi-Cal members as compared to the non-Medi-Cal population. The differences, however, were largest among African Americans, Other/Unknown, and Whites.

**Figure**

![Infant Mortality per 1,000 Medi-Cal and non-Medi-Cal Infants, by Race/Ethnicity, 2010](image)

Note: Rates for Native Americans were not shown due to small numbers. Rates for the groups “Other” and “Unknown” as well as “Asian” and “Pacific Islander” were combined to get more reliable rates.

Health Disparities in the Medi-Cal Population

The field of public health can be proud of its successes with vaccines—smallpox has been eradicated and other serious diseases are now much less of a threat. Indeed, vaccines may be our best defense against infectious diseases. The success story of vaccines also has some unintended side effects. With many infectious diseases becoming rare, many people see these as less of a threat and decide not to vaccinate their children. In addition, fears about side effects of vaccines have resulted in public protests about the dangers of vaccination, resulting in a growing number of parents not vaccinating their children.

The *Let's Get Healthy California Task Force Final Report* showed that vaccination rates for all doses of recommended vaccines among California children aged 19 to 35 months was about 68%, slightly lower than the national rate of 70%. Medi-Cal claims and encounter data could not provide a directly comparable measure to the overall California rate, but it was possible to evaluate if racial/ethnic disparities might exist. The Figure shows that Asians/Pacific Islanders and Latinos were slightly more likely to be vaccinated as compared to African Americans and Whites. Although Medi-Cal quality reports have shown relatively low immunization rates among Medi-Cal members, it is likely that some of the low immunization rates shown in the Figure are at least partially related to incomplete claims and encounter data within this domain.

Link to Data Sources and Methods
Adverse Childhood Experiences (ACE) include psychological, physical and sexual abuse, neglect, and other family dysfunction experienced before the age of 18. Studies have shown a strong dose-response relationship between ACEs and negative health outcomes, including risky behaviors, mental disorders, physical illness, overall poor quality of life, and early death.\(^1-3\) Research has noted that ACEs are widely prevalent among California’s general adult population.\(^4\) It is therefore important to prevent ACEs.

Among adult Californians, Whites and Latinos reported higher rates of experiencing at least one type of ACE and Asians/Others reported the lowest rates (see Figure).

A similar pattern was found in the California adult Medi-Cal population with Whites and Latinos reporting higher rates of experiencing at least one type of ACE than African Americans and Asians/Others. With the exception of Whites, all race/ethnicity rates of ACEs were slightly higher for the statewide California population than in the Medi-Cal population.

Education in general is likely to be associated with health outcomes later in life. A recent meta-analysis found a clear association between education and health that cannot be explained by income, employment, or family background. Educational achievement in turn may be related to early success with reading. For example, reading proficiency at the end of third grade is associated with high school graduation.

Third grade may be a transition point when kids start to use reading as a tool for learning, and students with less proficiency may have a difficult time performing well across academic subjects.

In 2012, 48% of third graders were reading at an advanced or proficient level (boys 45%; girls 50%). Education data were not specific to the Medi-Cal population, but reports from the Standardized Testing and Reporting system were available for “economically disadvantaged” and “not economically disadvantaged” as well as by race/ethnicity. The California Department of Education classifies children as economically disadvantaged if they participate in the free or reduced price meal program, or if their parents’ education level was coded as “not high school graduate.” All economically disadvantaged third graders, regardless of race/ethnicity, experienced much lower reading proficiency rates as compared to those who were not economically disadvantaged (see Figure). Asians had the highest proficiency rates, followed by Whites.

**Figure**

**Percentage of Third-Graders Advanced or Proficient at Reading, by Economic Status and Race/Ethnicity, 2012**

Asthma is the most prevalent condition among infants and children up to age 17.\textsuperscript{1,2} There are nearly 1.5 million children in California that have asthma, and the condition makes it difficult for this group to exercise, play, and attend school.\textsuperscript{3} The causes of asthma are complex, but there are risk factors such as exposure to air pollution that are at least partially modifiable.\textsuperscript{4}

There is evidence that children unable to manage their asthma tend to utilize emergency departments (ED) at increased rates.\textsuperscript{5} As such, better management of this chronic disease is critical to reducing ED visits and improving the quality of life for children with asthma.\textsuperscript{6}

The statewide ED visit rate for asthma was 73.0 per 10,000 children aged 0 to 17. This was similar to the rate for the Medi-Cal population of 72.6 per 10,000.\textsuperscript{7} As with Californians overall,\textsuperscript{3} there were strong racial/ethnic disparities among children in the Medi-Cal program. For example, African Americans were over eight times more likely than Asians/Pacific Islanders to visit the ED for asthma-related complications (see Figure below).

Link to Data Sources and Methods

Physical activity is associated with many positive health outcomes.¹ For children, it is important to develop an active lifestyle in the early years of life, since habits from early childhood through adolescence may influence habits in adulthood.² Moreover, the increasing prevalence of childhood obesity suggests that poor diet and physical inactivity need to be improved for immediate health impacts.³

California students in grades five, seven, and nine receive a physical fitness test called the FITNESSGRAM®. The six-part test is used to evaluate levels of fitness that offer protection from diseases associated with inactivity. The test showed that children categorized as “economically disadvantaged” or “not economically disadvantaged” differ in their ability to complete all of the six fitness requirements.⁴ The California Department of Education classifies children as economically disadvantaged if they participate in the free or reduced price meal program, or if their parents’ education level was coded as “not high school graduate.”

As shown in the Figure below, economically disadvantaged children—those more likely to be in the Medi-Cal system—were less likely to complete all six of the fitness requirements. In addition, there were substantial disparities by race/ethnicity. Native Americans, Pacific Islanders, Latinos, and African Americans were less likely to meet all six fitness requirements as compared to Whites and Asians.

Health Disparities in the Medi-Cal Population

Adolescent Physical Activity

In the 2008 Physical Activity Guidelines for Americans, the United States Department of Health and Human Services recommended that children and adolescents engage in at least one hour of moderate or vigorous physical activity each day. In fact, there is strong evidence that physical activity reduces the risk of chronic diseases (diabetes, cardiovascular disease, obesity, etc.), depression, and anxiety, and leads to favorable body composition in children and adolescents. Meeting this recommendation can lead to better health outcomes.

Among California adolescents, males were more likely to meet the physical activity guidelines for aerobic physical activity of at least one hour of moderate or vigorous physical activity each day compared to females (see Figure).

In the Medi-Cal population, there was a similar pattern with males being more likely to meet the physical activity guidelines for aerobic physical activity compared to females. Regardless of gender, the Medi-Cal population reported higher rates of physical activity than California adolescents as a whole.

Figure

Proportion of Adolescents Who Meet Physical Activity Guidelines for Aerobic Physical Activity Among California and Medi-Cal Populations, by Gender, 2009

Source: AskCHIS, California Health Interview Survey, 2009.

Health Disparities in the Medi-Cal Population

Adolescent Soda and Sweetened Beverages Consumption

Sugar-sweetened beverages (SSBs), like sodas and energy drinks, are the largest source of added sugar and are associated with increased rates of obesity and other chronic health conditions.1-3 Adolescents consume the most SSBs compared to other age groups.2-3 Research has noted that adolescents who drink more SSBs are more likely to eat high-calorie, low-nutrient foods.1 Some studies have shown that the intake of SSBs among California adolescents has increased in the past decade.4-5

Among California adolescents, the Multiracial group and Latinos were most likely to consume two or more SSBs a day, while Whites and Asians/Others were the least likely (see Figure).

In the California Medi-Cal population, Latino adolescents were most likely to drink two or more SSBs a day as compared to White and African American adolescents. Except for African Americans, Medi-Cal adolescents reported higher rates of SSBs than the general California adolescent population. Due to small sample sizes, however, the percentages for Multiracial and Asian/Other adolescents were statistically unstable and un-reportable.

Figure

Percent of California and Medi-Cal Adolescents Who Reported Drinking 2 or More Sweetened Beverages a Day, by Race/Ethnicity, 2009

Source: AskCHIS, California Health Interview Survey, 2009.
*Statistically unstable

It is recommended that teens eat 3.5 to 6.5 cups of fruits and vegetables each day depending on their age, sex, and physical activity level. Most vegetables and fruits are major contributors of certain nutrients that are under-consumed in the United States, including folate, magnesium, potassium, dietary fiber, and vitamins A, C, and K. Consumption of vegetables and fruits is also associated with a reduced risk of many chronic diseases, may be protective against certain types of cancer, and may help teens achieve and maintain a healthy weight.

Among Californians, adolescent males were more likely to report eating 5 or more servings of fruits and vegetables a day compared to females (see Figure).

Conversely, in the California Medi-Cal population, adolescent females were more likely to report eating 5 or more servings of fruits and vegetables a day compared to adolescent males. Regardless of gender, the Medi-Cal population reported less daily consumption of fruits and vegetables compared to the general California population.

---

**Figure**

*Rate of Consuming 5 or More Servings of Fruits and Vegetables per Day Among California and Medi-Cal Adolescents, by Gender, 2009*

Source: AskCHIS, California Health Interview Survey, 2009.

---

According to a 2012 Institute of Medicine report, obese youth are likely to be obese in adulthood. This report also stated that overweight youth were at greater risk for other health problems, including type 2 diabetes, hypertension, asthma, early maturation, and orthopedic problems.¹ Recently, several chronic diseases which had originally been considered “adult onset” are now appearing at younger ages, including type 2 diabetes and elevated blood pressure.¹-² Lastly, research has noted that obesity can vary by gender.³

Body Mass Index (BMI)-for-age charts are recommended to assess weight in relation to stature for children aged 2 to 20. Adolescents aged 12 to 17 were considered obese if they had a BMI equal to or greater than the 95th percentile. Among adolescent Californians, males reported higher rates of being obese than females (see Figure).

Among California Medi-Cal adolescents, females reported higher rates of being obese than males. In addition, the Medi-Cal adolescent population was more likely to be obese than California adolescents in general.

---

Overall health status is a self-reported measure of a person’s perceived health over time. Research has shown that health status is related to chronic diseases (e.g., vascular events, depression, and cancer)\textsuperscript{1-3} and the risk factors for chronic diseases (e.g., stress and physical activity).\textsuperscript{4-5} Analysis of health status can identify subgroups with poor perceived health, assist in guiding interventions to improve their situations, and avert more serious consequences.\textsuperscript{6}

In California, the Multiracial group was more likely to report that their overall health status was good, very good, or excellent (90.4%), followed by Whites (90.0%), Asians/Others (84.5%), African Americans (83.5%), and Latinos (77.3%) (see Figure).

In the California Medi-Cal population, the Multiracial group again was more likely to report that their overall health status was good, very good, or excellent (80.0%), followed by Latinos (78.6%), African Americans (74.7%), Whites (73.9%), and Asians/Others (60.3%). Regardless of race/ethnicity, the Medi-Cal population reported lower rates of overall health status than the general California population.

### Overall Health Status

Overall health status is a self-reported measure of a person’s perceived health over time. Research has shown that health status is related to chronic diseases (e.g., vascular events, depression, and cancer)\textsuperscript{1-3} and the risk factors for chronic diseases (e.g., stress and physical activity).\textsuperscript{4-5} Analysis of health status can identify subgroups with poor perceived health, assist in guiding interventions to improve their situations, and avert more serious consequences.\textsuperscript{6}

In California, the Multiracial group was more likely to report that their overall health status was good, very good, or excellent (90.4%), followed by Whites (90.0%), Asians/Others (84.5%), African Americans (83.5%), and Latinos (77.3%) (see Figure).

In the California Medi-Cal population, the Multiracial group again was more likely to report that their overall health status was good, very good, or excellent (80.0%), followed by Latinos (78.6%), African Americans (74.7%), Whites (73.9%), and Asians/Others (60.3%). Regardless of race/ethnicity, the Medi-Cal population reported lower rates of overall health status than the general California population.

### Figure

**Rate of Californians and Medi-Cal Population Who Reported Their Overall Health was Good, Very Good, or Excellent, by Race/Ethnicity, 2009**

![Graph showing the rate of Californians and Medi-Cal population who reported their overall health was good, very good, or excellent, by race/ethnicity, 2009.]

Source: AskCHIS, California Health Interview Survey, 2009.

In the 2008 *Physical Activity Guidelines for Americans*, the United States Department of Health and Human Services recommended that adults engage in at least 150 minutes of moderate-intensity physical activity each week or 75 minutes a week of vigorous-intensity aerobics. Research has shown that physical activity can lower the risk of early death, coronary heart disease, stroke, high blood pressure, type 2 diabetes, breast and colon cancer, depression, and cognitive impairment in older adults.1

Among California adults, Whites were most likely to report 150 or more minutes of physical activity each week, while Latinos were the least likely (see Figure).

In the Medi-Cal adult population, Asians/Others and Whites were more likely to report 150 or more minutes of physical activity each week as compared to African Americans and Latinos. For all race/ethnicity groups except Asian/Other, the Medi-Cal population reported lower rates of physical activity than the general California adult population.

Health Disparities in the Medi-Cal Population

Hypertension Management

High blood pressure (hypertension) is a common condition that increases the risk of diseases such as heart disease and stroke.\(^1\)\(^2\) In addition, recent research has shown that hypertension may be linked to some types of dementia.\(^3\) Risk factors for hypertension include smoking, obesity, heavy alcohol consumption, and genetics.\(^4\) Fortunately, many of the risk factors are modifiable, and thus people can improve their blood pressure with lifestyle changes.\(^5\)\(^6\) Medications are also very effective at controlling high blood pressure.\(^7\) The *Let’s Get Healthy California Task Force Final Report* showed that between 50% to 79% of people with high blood pressure control it successfully.\(^8\)

Medi-Cal claims and encounter data suggested that about 7.23% of all members had an episode of care related to hypertension between July 1, 2011 and June 30, 2012. To identify possible disparities by race/ethnicity, the figure below shows the percent of hypertensive Medi-Cal members adherent to four types of prescribed medications used to manage hypertension. Whites and Asians/Pacific Islanders were slightly more likely to adhere to ACE-Inhibitors, Beta-Blockers, and Calcium Channel Blockers, while Native Americans and Asians/Pacific Islanders were slightly more likely to adhere to Angiotensin II Receptor Antagonists.

![Figure](Media/image.png)

**Figure**

Medi-Cal hypertension patients adherent to prescribed medications, by race/ethnicity, 2011-12

Health Disparities in the Medi-Cal Population

According to a 2012 Institute of Medicine report, two-thirds of adults in the United States are overweight or obese and the proportion of those who are obese has more than doubled since 1976-1980. Some of the health consequences of obesity include high blood pressure, high cholesterol, cardiovascular disease, and diabetes.\(^1\) Many of the health care costs of these chronic diseases are paid for with public dollars. It has been estimated that total Medicare and Medicaid spending reductions would be 8.5% and 11.8%, respectively, in the absence of obesity.\(^2\)

Adults with a Body Mass Index (BMI) of 25 to 29.9 are defined as overweight and those with a BMI of 30 and above are classified as obese. Among adult Californians, Latinos and African Americans reported higher rates of being overweight and obese than Whites and Asians/Others (see Figure).

In the adult Medi-Cal population, Latinos and Asians/Others reported higher rates of being overweight than Whites and African Americans. The highest rates for obesity were among Whites and African Americans and the lowest was among Asians/Others. Medi-Cal adults were more likely to report being overweight than California adults only in the Asian/Other population. Regardless of race/ethnicity, however, Medi-Cal adults were more likely to report being obese compared to California adults. Due to the small number of Asian/Other adults in the sample, results for this group should be interpreted with caution.

**Link to Data Sources and Methods**

Fall 2013
Depression involves five or more symptoms such as sad mood or diminished interest that are continuously present for at least two weeks. Depression among adolescents is influenced by stressful events and changes associated with maturing, sex hormones, and interpersonal conflicts. Research has shown that adolescent girls are twice as likely as boys to experience depression.

The Let’s Get Healthy California Task Force Final Report provided survey data that suggested about one-third of 7th, 9th, and 11th graders experienced sad or hopeless feelings in the past 12 months. In a national survey, 8.0% of 12 to 17 year olds reported a “major depressive episode.” Unfortunately, one report suggested that only 38.9% of adolescents who experienced at least one major depressive event in the last year received treatment for major depression.

Medi-Cal claims and encounter data suggested that about 1.7% of adolescents between the age of 12 and 17 received medical treatment for depression. Although possibly related to data quality problems such as incomplete reporting of managed care encounter data, there were racial/ethnic disparities associated with treatment of depression (see Figure). Native Americans and Whites were more likely than other groups to receive treatment for a major depression event. The rate for Asians and Pacific Islanders was substantially lower.

**Link to Data Sources and Methods**
Depression involves five or more symptoms such as sad mood or diminished interest that are continuously present for at least two weeks. Major depression affects between 5% and 10% of patients in primary care settings, and often goes undiagnosed and untreated. Depression has negative impacts on interpersonal relationships and one’s ability to perform in the workplace. In addition, depression is associated with suicide and other adverse health behaviors such as smoking, alcohol consumption, physical inactivity, and sleep disturbance.

The *Let’s Get Healthy California Task Force Final Report* reported that 6% of California adults have experienced a Major Depressive Episode. Medi-Cal claims and encounter data suggested that about 4.9% of adults (aged 18-64) received some type of medical treatment for depression. Although possibly related to data quality problems such as incomplete reporting of managed care encounter records, there were racial/ethnic disparities associated with treatment of depression (see Figure). Whites and Native Americans were more likely than other groups to receive treatment for a major depression event. The rate for Asians and Pacific Islanders was substantially lower.

Health Disparities in the Medi-Cal Population

Colorectal cancer involves abnormal cell growth in the colon or rectum. Following lung cancer, colorectal cancer is the second leading cause of cancer death in the United States. Risk factors include age, presence of polyps, personal/family history, diet, exercise, and smoking.\(^1\)

Colorectal cancer screening includes sigmoidoscopy, colonoscopy, and fecal occult blood testing to detect problems before symptoms emerge.\(^2\) There is evidence that colorectal cancer screening saves lives.\(^1,3\) Given this evidence, the U.S. Preventive Services Task Force recommends colorectal cancer screening for men and women aged 50 to 75.\(^1\)

Claims and encounter data from the Medi-Cal data warehouse were used to create a Healthcare Effectiveness Data and Information Set (HEDIS) quality indicator to measure patients 50 to 75 years of age that received appropriate screening for colorectal cancer (see Figure). Screening rates were substantially higher for Asians/Pacific Islanders as compared to the other racial/ethnic categories.

Palliative care programs help people and their families manage the pain and stress of serious diseases rather than to treat or seek a cure. As a specialized type of medical care, palliative care can increase patients’ quality of life and in some instances extend life. It can also provide options about how and where to manage terminal illnesses.\(^1\) Studies showed that palliative care programs can reduce costs.\(^1^-^3\) Based on surveys of California hospitals, between 2007 and 2011, pediatric palliative care increased by 128% and adult palliative care increased by 24%. In 2011, 53% of California hospitals had some type of palliative care program.\(^1\)

It is important to understand the degree to which Medi-Cal members have access to palliative care. One important initiative has led to a 3-fold increase in palliative care programs in California public hospitals (from 4 to 12).\(^4\) The Figure below shows the number of hospitals in three groups categorized by the number of Medi-Cal hospital discharges per year. The Figure then shows the proportion of the hospitals with palliative care programs.\(^5\) For example, there were 185 hospitals with between 500 and 5,000 Medi-Cal discharges per year, and within this group, 96 (52%) of the hospitals had a palliative care program. Hospitals that treat a large number of Medi-Cal members each year generally have palliative care programs.

Health Disparities in the Medi-Cal Population

Preventable Hospitalizations

When conditions like diabetes, congestive heart failure, and asthma are managed properly in ambulatory care settings, fewer people experience acute complications that require inpatient hospitalization. Thus, many hospitalizations are preventable as a result of better access to high-quality outpatient care.

The Let's Get Healthy California Task Force Final Report provided an overall California rate of 1,243 preventable hospitalizations per 100,000 people (age-sex adjusted). For the Medi-Cal population, however, the unadjusted preventable hospitalization rate was slightly higher at 1,290 per 100,000.

Preventable hospitalizations for the Medi-Cal population are presented by race/ethnicity in the Figure below. African Americans had the highest rates, followed by Whites, Asians/Pacific Islanders, Latinos, Native Americans, and Others.

Figure

Preventable Hospitalizations per 100,000 Medi-Cal Members, by Race/Ethnicity, 2011

Note: Rates produced from the Agency for Healthcare Research and Quality (AHRQ) Prevention Quality Indicators Composite, Version 4.4. Members eligible for both Medicare and Medicaid were excluded.

A large proportion of hospital readmissions are attributed to people with chronic diseases such as congestive heart failure and diabetes. Research suggests that hospital readmissions are both costly and potentially dangerous to patients. Fortunately, there is evidence that hospital readmissions can be reduced through better coordination of care. For example, clear discharge instructions and post-discharge communication may help patients better manage their own health and prevent acute episodes that require re-hospitalization. Evidence is leading to policy changes. Medicare is reducing payment for specific readmissions and Medi-Cal has started a Statewide collaborative to reduce All-Cause Readmissions using quality improvement projects.

The *Let’s Get Healthy California Task Force Final Report* provided an overall California readmission rate of 14.1%. The hospital readmission rate for the Medi-Cal population was higher at 18.7%.

Readmission rates vary by race/ethnicity, yet the differences were the most striking for the Medi-Cal population. For example, although there was only a small difference between the Medi-Cal and non-Medical population among Native Americans, the readmission rates were substantially different for Whites. African Americans, Latinos, Asians/Pacific Islanders, and Others also had higher rates among the Medi-Cal population, yet the relative difference was not as extreme as among Whites.

Hospital care offers people many opportunities for improved health. However, hospital care can be potentially dangerous with a possible 98,000 or more people dying each year in the United States from hospital-acquired conditions.¹ Hospital-acquired infections—one important category of hospital-acquired conditions—are expensive with an estimated national cost between $38 and $45 billion dollars each year.²

Numerous initiatives at the state and federal levels are striving to reduce hospital-acquired infections, and quality improvement programs have shown great potential to reduce hospital-acquired conditions.³

Hospital-acquired conditions averaged 0.75 per 1,000 hospital discharges for the California non-Medi-Cal population and 0.84 per 1,000 discharges for Medi-Cal members.⁴ The rates among racial/ethnic groups for the non-Medi-Cal populations are relatively similar. Within the Medi-Cal population, however, there are larger differences between racial/ethnic groups. The racial/ethnic category Other, and to a lesser extent Native Americans, have relatively higher rates as compared to African Americans, Whites, Latinos, and Asians/Pacific Islanders.

Health Disparities in the Medi-Cal Population

In the 2008 Physical Activity Guidelines for Americans, the United States Department of Health and Human Services recommended that children and adolescents engage in at least one hour of moderate or vigorous physical activity each day. Decreased physical activity and an increased sedentary lifestyle have led to increased obesity and chronic diseases (e.g., diabetes and hypertension) among youth. Walking and biking to and from school is one way for children and adolescents to meet this recommendation, and if followed, can lead to better health outcomes.1

Among California youth, Latinos and African Americans were most likely to walk, bike, or skate to and from school in the past week, while Whites and Asians/Others were the least likely (see Figure).

In the Medi-Cal population, there was a similar pattern with Latino and African American youth being most likely to walk, bike, or skate to and from school in the past week as compared to Multiracial, White, and Asian/Other youth. Regardless of race/ethnicity, the Medi-Cal population reported higher rates of physical activity than the California youth population.

Poor neighborhood safety has been associated with poor health outcomes in adults. Research has shown that a lack of neighborhood safety is associated with obesity, low physical activity, increased tobacco use in pregnant women, depression in Korean adults, and decreased adherence to diabetes self-management among adult type 2 diabetics. Overall, adults who perceive their neighborhoods to be unsafe may be less able to participate in low-cost activities (i.e., walking) and may experience increased stress. These factors may in turn lead to maladaptive coping and an inability to manage their health.

In California, White adults were more likely to report feeling safe in their neighborhood all or most of the time (95.5%), followed by the Multiracial group (94.1%), Asians/Others (89.9%), African Americans (86.3%), and Latinos (84.9%) (see Figure).

In the California Medi-Cal population, White adults were more likely to report feeling safe in their neighborhood all or most of the time (88.4%), followed by African Americans (81.2%), the Multiracial group (80.4%), Asians/Others (79.9%), and Latinos (78.3%). Regardless of race/ethnicity, the Medi-Cal population reported lower rates of feeling safe in their neighborhood as compared to the general California population.
